Abstract

We experimentally demonstrate that supersaturated solution of sodium acetate, commonly called ‘hot ice’, is a massively-parallel unconventional computer. In the hot ice computer data are represented by a spatial configuration of crystallization induction sites and physical obstacles immersed in the experimental container. Computation is implemented by propagation and interaction of growing crystals initiated at the data-sites. We discuss experimental prototypes of hot ice processors which compute planar Voronoi diagram, shortest collision-free paths and implement AND and OR logical gates.

Keywords: crystallization, Voronoi diagram, shortest path, unconventional computing, logical gates, physics of computation

1 Introduction

The last decade has witnessed a rise in the number of unconventional computing devices based on principles and mechanisms of information processing in physical, chemical and biological systems [11]. Most results in unconventional computing are theoretical [14, 15] whilst there is a handful of intriguing experimental prototypes. The experimental laboratory research focuses on implementation of computing schemes in novel materials which helps us to grasp the inner nature of physics of computation. The following prototypes, or their families, give us a good representation of novel computing substrates.

Reaction-diffusion computers are implemented in a spatially extended chemical media. Data and results of computation are represented by spatial distributions of reagent concentrations. Computation is realized by propagating and interacting diffusive or excitation waves [1]. Experimental laboratory prototypes

of reaction-diffusion computers solve a wide range of geometrical problems, optimization and logical computation [1].

Physarum computing is based on adaptive foraging behaviour of plasmodium of *Physarum polycephalum*. In *Physarum* computers data are represented by the distribution of attracting (food) and repelling sources (light). Computation is implemented by the plasmodium which optimizes its feeding pattern under control of attracting/repelling forces. Results of the computation are represented by the morphological structure of the plasmodium [25, 26, 7, 13].

Extended analog computers represent data as a spatial configuration of point-wise sources of current applied to a conductive medium. Computing operations are determined by physical properties of the conductive medium, (e.g. foam or gel). Results are represented by the distribution of voltages across the medium [24].

Other less-known prototypes include analog computing schemes using microwaves [20], plane tessellation in gas-discharge semi-conductor systems [10], learning networks of memristors [31], logical circuits in liquid crystals [22], and glow discharge systems computing the shortest path [27].

Most experimental prototypes of unconventional computers either require a tailored hardware interface (analog computers, liquid crystals) and specialized equipment (memristors, gas-discharge systems), or they may have intrinsic limitations on the speed of computation (reaction-diffusion chemical processors). *Physarum* computer is the simplest to build but the most difficult to control, due to the sensitivity and somewhat unpredictable behaviour of the living creature.

We aim, therefore, to provide an example of a novel computing material which is cheap to build, requires minimal resources to operate, implements computational procedures relatively quickly and is capable of solving a wide range of computationally-hard tasks. We show that sodium acetate trihydrate (colloquially called ‘hot ice’ due to its resemblance to ice and its crystalline behaviour) perfectly fits our specification of an ‘ideal DIY unconventional computer’ because it solves a variety of tasks by traveling and interacting waves of crystallization in its supersaturated solution.

The paper is structured as follows. Experimental methods are outlined in Sect. 2. Section 3 presents experimental results on computing the Voronoi diagram. In Sect. 4 we show how to extract direction towards the site of crystallization induction. Computation of one-destination-many-sources paths by crystallization of sodium acetate, and further extraction of a collision-free shortest path, are discussed in Sect. 5. Experimental implementation of logical gates is presented in Sect. 6. We summarize the findings and discuss further developments in Sect. 7.

2 Methods

We prepare a supersaturated clear solution of sodium acetate trihydrate $\text{CH}_3\text{COONa}\cdot 3\text{H}_2\text{O}$, pour the hot solution into Petri dishes and cool the solution down to -5°C . To induce crystallization we briefly immerse aluminum

wire (powdered with fine crystals of the sodium acetate) into the solution.

To compute shortest paths in a space with obstacles we mimic obstacles with blobs of silicon, small Petri dishes fixed to the bottom of experimental container and labyrinths made of Blu-Tack[®]¹.

Dynamics of crystallization is recorded with FujiPix 6000 digital camera and still high-resolution images are produced by scanning containers with crystallized sodium acetate in HP Deskjet 5100 scanner. Magnified images of the crystalline structure formed are taken using Digital Blue[®] QX-5 USB microscope.

Software tools for extracting directions of crystal growth from still images and models of cellular-automaton shortest path calculation are coded in Processing².

3 Voronoi diagram

Let $\mathbf{P}$ be a nonempty finite set of planar points. A planar Voronoi diagram of $\mathbf{P}$ is a partition of the plane into such regions, that for any element of $\mathbf{P}$, a region corresponding to a unique point p contains all those points of the plane which are closer to p than to any other node of $\mathbf{P}$. A unique region $vor(p) = \{z \in \mathbf{R}^2 : d(p, z) < d(p, m) \forall m \in \mathbf{R}^2, m \neq z\}$ assigned to point p is called a Voronoi cell of the point p . The boundary of the Voronoi cell of a point p is built of segments of bisectors separating pairs of geographically closest points of the given planar set $\mathbf{P}$. A union of all boundaries of the Voronoi cells determines the planar Voronoi diagram: $VD(\mathbf{P}) = \cup_{p \in \mathbf{P}} \partial vor(p)$ [28, 23].

A basic concept of parallel approximation of Voronoi diagram by wave patterns propagating in a spatially extended medium [2] is based on time-to-distance transformation. To compute a bisector separating two given points p and q we initiate wave-patterns in the medium's sites geographically corresponding to p and q . The waves travel the same distance from the sites of origination before colliding. The loci where the waves meet indicate sites of the computed bisector.

Precipitating reaction-diffusion chemical media are proved to be an ideal computing substrate for approximation of the planar Voronoi diagram [30, 18, 1]. A Voronoi diagram can be approximated in a two-reagent medium. One reagent α is saturated in the substrate, drops of another reagent β are applied to the sites corresponding to planar points to be separated by bisectors. The reagent β diffuses in the substrate and reacts with reagent α . Colored precipitate is produced in the reaction between α and β . When two or more waves of diffusing α meet, no precipitate is formed [18]. Thus uncolored loci of the reaction-diffusion medium represent bisectors of the computed diagram.

Most reaction-diffusion chemical processors are quite slow in computing a Voronoi diagram at the macro-scale, due to speed limitations caused by diffu-

¹Bostik Ltd., <http://www.bostik.co.uk/>

²www.processing.org

sion. Crystallization patterns in sodium acetate propagate much quicker and thus could improve speed limitations of existing reaction-diffusion algorithms.

We represented data points of set $\mathbf{P}$ by a configuration of pins (pieces of aluminium wire) fixed through the lid of a 9 cm Petri dish (Fig. 1a). The pins were powdered with fine crystals of sodium acetate.

To start computation we place the lid on the dish with the supersaturated solution. The pins become immersed into the solution. They induce crystallization. Patterns of crystallization propagate – as classical target waves – from the sites of crystallization induction.

A crystallization wave stops when it encounters another wave of crystallization (Fig. 1bc). Boundaries between stationary patterns of crystallization represent edges of planar Voronoi diagram $VD(\mathbf{P})$. The experimental boundaries perfectly correspond to bisectors of the diagram computed by the classical Fortune’s sweepline algorithm [21] (Fig. 1d).

4 Detecting directions towards sites of crystallization induction

Crystals growing from nucleation sites bear distinctive elongated shapes expanding towards their proximal ends (Fig. 2a). Not only a crystal’s overall shape but also the orientation of saw-tooth edges indicate the direction of the crystal’s growth (Fig. 2b).

The direction of crystal growth can be detected by conventional image processing techniques, e.g. edge detection procedures (Fig. 2), or by a complementary method of detecting directional uniformity of image domains as discussed below.

We detect local directions of crystal grows in the following way. A fine grid of nodes is applied onto given image and for every node x of the grid we calculate a set $\mathbf{V}$ of vectors of length r originating at x and directed at angles $\alpha \in \{0, 0.1, 0.2, \dots, 2/\pi\}$. For each vector $v \in \mathbf{V}$ we calculate a sum of standard deviations $\sigma(v)$ of RGB colors of the image pixels coinciding with v . A vector $v' = \min_{v \in \mathbf{V}} \sigma(v)$ with minimal sum of color deviations indicates a local direction of crystallization propagation. A configuration of local direction vectors, $r = 20$, is shown in Fig. 2d.

The vector configuration represents sinks determined by points from set $\mathbf{P}$. If we place a mobile agent at any site but bisectors of the vector configuration Fig. 2d the agent will be attracted to the closest data point p . This leads us to another problem solvable with sodium acetate — computation of a collision-free shortest path in a space with obstacles.

5 Computation of a collision-free path

Previously [3] we have designed a cellular-automaton algorithm for constructing one-destination-many-sources shortest path. The automaton is a regular array

Figure 1: Computation of Voronoi diagram by crystallization of sodium acetate: (a) configuration of pins representing data points $\mathbf{P}$, (b) photograph and (c) scanned image (sites where crystallization was induced are encircled) of crystal structure induced by the pins, (d) planar Voronoi diagram of $\mathbf{P}$ computed by classical algorithm. See video of the experiment at [8].

Figure 3: Computation of shortest paths to a single destination: (a) example of pointer orientation (resting cells are gray, excited cell is marked with '+', and refractory cells with '-'), (b) example of pointer configuration in presence of obstacles and three shortest paths (bullets) to the site of initial excitation; orientation of cell pointers is shown explicitly.

of finite state machines (cells) which takes discrete states and update their states simultaneously and in discrete time depending on the states of its closest neighbors. Here we consider hexagonal array of cells. Each cell has six neighbors and takes three states — resting, excited and refractory. A resting cell becomes excited if it has at least one excited neighbour. An excited cell switches to a refractory state, and refractory cell returns to resting state independently on states of its neighbors. When we excite one cell of a resting array a wave of excitation is initiated. The excitation wave propagates in the array.

To store the computed path we supply every cell with a pointer. Pointers in all cells are set to nil initially. When a cell becomes excited its pointer orients towards the direction from where the excitation wave came. An example is shown in Fig. 3a.

Obstacles are imitated by always-resting, or non-excitabile, cells. Examples of the pointer configuration and shortest collision-free paths are shown in Fig. 3b. A cell assigned to be a destination (in the north-west corner of the array Fig. 3b) is excited. Waves of excitation propagate from the site of initial stimulation. The waves spread around obstacles and disappear in the absorbing boundaries of the array. The excitation waves induce orientation of cell pointers (Fig. 3b). Array of pointers represents a set of shortest collision-free paths from any cell (source) of the array to the site of initial excitation (destination). Three such paths are shown in Fig. 3b.

As we demonstrated in Sect. 4 longitudinal crystals growing in sodium acetate are physical analogs of pointers indicating from where — locally — the wave of crystallization came from. That is crystallization of sodium acetate is the physical implementation of the original cellular-automaton algorithm [3] for computation of shortest collision-free path.

Let us consider experimental realization. We represent obstacles by impenetrable barriers and induce crystallization at a single site of the medium. For demonstration purposes we have tested various types of objects to represent obstacles, including 35 mm Petri dish glued with silicon to a bottom of larger Petri dish (Fig. 4a) and blob of silicon (Fig. 4b) to make simple obstacles, and Blu-Tack[®] to make more complex obstacles (Fig. 4c) and a labyrinth (Fig. 4d).

From the images (Fig. 4) we calculate a configuration of local vectors (Fig. 5). A vector at each point indicates the direction from where the wave of crystallization came from. The vectors represent an attracting field, which ‘pulls’ virtual objects, placed in the field, towards the destination (site of initial disturbance). We found that the attracting field is approximated by the vectors satisfactory for a wide range of vector parameters: vector grid steps 5 (Fig. 5c), 10 (Fig. 5a) and 20 (Fig. 5bd), and vector length 20 (Fig. 5d), 20 (Fig. 5ab) and 50 (Fig. 5c).

To check whether vector configurations extracted from scanned images of crystallized sodium acetate provide sufficient representation of many-sources-one-destination shortest paths we employed pixelbots [6]. A pixelbot is a virtual pixel-sized automaton. The pixelbot moves along the direction of nearest non-zero vector. The pixelbot imitates a tiny (2-5 mm) in diameter robot which travels along sodium acetate crystals or in the longitudinal grooves between the crystals. If there are no non-zero vectors in the pixelbot’s neighborhood the pixelbot moves at random [6].

Examples of test-run trajectories of pixelbots traveling in the vector configurations are superimposed on scanned images of crystallized sodium acetate in Fig. 6. Pixelbots easily reach the destination in the case of simple obstacles (Fig. 6ab). They spent more time wandering at random in arenas with complex obstacles (Fig. 6c). Pixelbots do not perform well in a maze (Fig. 6d): in some parts of the maze pixelbots navigate satisfactory and travel for substantial distances (see trajectories in the western half of image Fig. 6d), in other parts they become stuck forever falling into indefinite loops of repetitive motion (eastern half of image Fig. 6d).

Figure 4: Scanned images of crystallization of sodium acetate occurred in shallow dishes with impenetrable obstacles: (a) 35 mm Petri dish glued to the bottom of the container, (b) blob of silicon, and complex obstacles (c) and maze (d) made of Blu-Tack[®]. Sites of crystallization induction (destinations of shortest paths) are encircled. See videos of the experiments at [8].

6 Implementation of AND and OR logical gates

We implement logical gates in a geometrically constrained, T-shaped, containers with sodium acetate. Shoulders of a T-shaped container represent inputs x and y and vertical stem — output z . When we induce crystallization in any one or both shoulders the whole solution in the T-shaped container, including z -output, becomes crystallized. Assuming liquid phase represents logical TRUE and solid phase logical FALSE, sodium acetate in T-shaped container implements OR gate.

If we induce crystallization in both shoulders of the container crystallization waves collide at a junction and form a boundary in result of the collision (Fig. 7). If crystallization is induced only in one of the shoulders no boundary is formed in z -output. This hints to the following interpretation. Presence/absence of crystals in shoulders x and y represent TRUE/FALSE. Presence/absence of boundary (bisector of crystallization induction sites in x and y) represents $z = \text{TRUTH}/\text{FALSE}$. In such interpretation sodium acetate in T-shaped container implements AND gate.

7 Discussion

We experimentally demonstrated that crystals growing in supersaturated solution of sodium acetate ('hot ice') compute planar Voronoi diagram, approximate set of collision-free shortest paths in a space with obstacles and implement Boolean conjunction and disjunction in a geometrically constrained medium.

Every micro-volume of the sodium acetate solution can input external stimuli/data, participate in crystal growth and represent a boundary between collided waves of crystal growth. Data are inputted in the sodium acetate solution in parallel, e.g. we use a set of pins to input planar point set to compute a Voronoi diagram. Results of computation are also read in parallel, e.g. using optical recording. A micro-volume of the solution can be removed or added prior to computation, this is the sign of fault-tolerance. Therefore supersaturated solution of sodium acetate is a massively-parallel fault-tolerant computer.

With regards to Voronoi diagram computation the hot ice computer is a highly accelerated version of precipitating reaction-diffusion chemical Voronoi processors [30, 16, 17, 18, 19]. We demonstrate in experiments that boundaries between crystal patterns perfectly represent edges of Voronoi diagram constructed on sites of crystallization induction. We did not show however how exactly the edges can be extracted from still images of the crystallized sodium acetate. This may be a topic of further studies.

In laboratory experiments we proved that hot ice computer approximates a set of many-source-one-destination collision-free shortest paths in a space with obstacles. The shortest path problem is a typical benchmark task for unconventional computing devices. There experimental evidences that shortest path can be computed in excitable chemical medium (Belousov-Zhabotinsky reaction) [9, 29], in precipitating chemical medium interfaced with cellular automaton [5], and in plasmodium of *Physarum polycephalum* [25].

Figure 7: Experimental implementation of AND gate in sodium acetate: (a) original scanned image of the crystallized sodium acetate, (b) contrast enhanced image, (c) scheme of the computation, two sites of crystallization induction (corresponding to TRUE values of input variables x and y) are encircled, bisector separating x and y is shown by a line.

These implementations, although very appealing, are however far from perfect. Some of them require substantial assistance of external hardware/software in the detection of the ‘intersection’ of waves initiated in source and destination sites [9, 29] or extraction of a shortest path [5], others just do not produce a directed path at all [25]. Hot ice computer physically represents a many-source-one-destination set of shortest paths, where destination is a site of crystallization induction. If there would be a mobile robot compatible in size with width of crystals, such a robot would find the destination from any site of crystal pattern just by following the orientation of crystals. However, our experimental implementation is not ideal: it is sometimes possible to take a wrong route or fall into cyclic route by following individual crystals. We will perfect the realization in future.

We demonstrated that two logical gates – AND and OR – are implemented in crystallization of sodium acetate solution. This construction complements experimental realization of XOR gate in precipitating reaction-diffusion chemical medium [4]. One drawback of our approach is that different properties of the medium represent values of output Boolean variables: liquid and solid phases in OR gate, and presence/absence of a bisector in AND gate. Thus, in principle, AND and OR gates cannot be cascaded. One can consider three valued variables, where liquid phase represents 0, crystal phase – c and bisector (a boundary between collided waves of crystallization) – b . Then a T-shaped container with sodium acetate implements the following binary composition $\star$:

$\star$	0	b	c
0	0	c	c
b	c	c	c
c	c	c	b

Whether such operation is useful for implementation of logical circuits or not will be studied elsewhere.

Finally we will say a few words about re-usability. In [1] we provide comparative analysis of existing non-linear medium computers in terms of re-usability.

All excitable processors, including Belousov-Zhabotinsky medium, are reusable chemical computers, because when development of excitation patterns is finished (and a dissipative structure of excitations representing result of computation recorded) the medium can be forced back to its resting state, thus being ready for next cycle of computation. However, excitable processors are memoryless, because they do not, as a rule, store results of computation in a non-volatile memory.

Precipitating chemical processors, e.g. [4], have memory. They represent results of computation in the spatial distribution of precipitate which, when dried, can stay unchanged for years. However, the precipitating chemical processors cannot be re-used. They are not re-usable but “disposable”.

Hot ice computer is an experimental example of re-usable non-linear medium processor with non-volatile memory. Patterns of crystallization, which represent results of computation, stay almost intact for weeks and months. As soon as

they are heated above 58°C the patterns are transformed into liquid phase, thus being ready for next cycle of computation.

Acknowledgment

I am indebted to Sebastian Adamatzky for pestering me into playing with the hot ice, and for participating in all experiments, and to Jeff Jones for editing text and participating in discussions.
